We present analytical solutions for the three-body problem with multichannel interactions and identify a class of quasibound Efimov states that can be viewed as three-body Fano-Feshbach resonances. Our method employs a multichannel generalization of the Fermi pseudopotential to model low-energy atom-atom interactions near a magnetically tunable Fano-Feshbach resonance. We discuss the conditions under which quasibound Efimov states may be supported and identify the interaction parameters that limit the lifetimes of these states. We speculate that it may be possible to observe these states using spectroscopic methods, perhaps allowing for the measurement of multiple Efimov resonances.

DOI: 10.1103/PhysRevA.78.020701 PACS number(s): 34.20.Cf, 31.15.xj

Three resonantly interacting particles can form long-range bound states, called Efimov states [1], even if the short-range interparticle interaction supports no two-body bound states. Such states are supported by an effective $R^{-2}$ dipole potential that strongly affects few-body processes at sufficiently low energies [2–4], particularly three-body recombination, which is known to control the lifetime of trapped ultracold gases [5]. It was only recently that the first strong experimental evidence of Efimov physics was found in an ultracold thermal gas of cesium atoms [6]. The observation [6] was made possible by utilizing a magnetically tunable Fano-Feshbach resonance to precisely control the two-body scattering length $a$ and by then observing a previously predicted [3,7,8] shape-resonant feature in the atom-loss rate due to three-body recombination. In this work, we identify a class of fully three-body Fano-Feshbach Efimov resonances embedded in the three-body continuum. Using a multichannel generalization of other models [2–4], we solve the adiabatic hyperspherical equations and analyze the resulting energy landscape.

Our model permits each atom to have multiple internal states, allowing for two-body and three-body scattering between different energy thresholds [9]. We note that Efimov states attached to excited three-body scattering thresholds are absent in single-channel models and difficult to infer from other multichannel approaches [10]. Here, our calculations show that these states are supported under the rather general stipulation that a quasibound two-body state is quasidegenerate with an excited two-body scattering threshold [11] (see Fig. 1). Given the rich structure of resonances in, for example, cesium [12], this condition could likely be satisfied.

We stress that these Efimov states are of a unique character in that they can be viewed as fully three-body Fano-Feshbach resonances embedded within the three-body continuum far above the energy of open channel collisions, in contrast with the single-channel Efimov resonances predicted and recently observed that were interpreted as shape resonances [3,7]. Since the scattering length $a$ for ground-state atoms will not in general be resonant, the gas will be comparatively stable with respect to the $a^4$ overall scaling law for three-body recombination [3,5,7].

Such Efimov states attached to excited thresholds could be directly accessed via photoassociation and observed through the measurement of the resulting atom-loss rates or photoabsorption spectrum. That is, photons could be used to form these trimers directly, resulting in resonant absorption, enhancement of three-body recombination, and atom loss, thus opening a new toolkit of powerful spectroscopic techniques [13].

We let each atom have two internal states (hyperfine or Zeeman) labeled $|1\rangle$ and $|2\rangle$ with energies $E_1=0$ and $E_2=\epsilon$, respectively, where the energy splitting $\epsilon$ is a magnetically tunable parameter. Hence, the scattering of two atoms can occur between different channels labeled by symmetric products of one-atom states: $\{|\sigma\rangle\} = \{|11\rangle, |(12)+|21\rangle\}/\sqrt{2}$ with respective threshold energies $\{E_{\sigma}\} = \{0, \epsilon, 2\epsilon\}$. Other two-body multichannel treatments [10] model Fano-Feshbach resonances by including a background scattering channel and a resonant molecule channel, but fail to treat the internal states of the atoms. In contrast, we label our channels explicitly by the internal states of the atoms and our Hamiltonian allows for scattering at excited energy thresholds between atoms in different internal states. Furthermore, this description is easily generalized to allow for more than two internal one-atom states.

As illustrated in Fig. 1, the zero-range $s$-wave two-body...
potential is now written in the $\{\ket{\sigma}\}$ basis as (in atomic units which are used throughout this Rapid Communication)

$$\psi(r) = \frac{4\pi A}{2\mu_{2B}} \delta^0(r) \frac{\partial}{\partial r} \Phi(r \cdot).$$  \hspace{1cm} (1)

where $\delta^0(r)$ is the usual three-dimensional Dirac-$\delta$ function and $\mu_{2B}=m/2$ is the two-body reduced mass. This interaction is the natural extension of the regularized Fermi pseudopotential which imposes the Bethe-Peierls boundary condition on the two-body wave function, $\psi(r \to C(1-a/r)$ as $r \to 0$. One may consider the matrix $A$ to be the multichannel generalization [14,15] of the scattering length $a$. When the channels in Fig. 1 are weakly coupled, $A$ is nearly diagonal with diagonal elements roughly representing background scattering lengths. More rigorous mathematical description is obtained from multichannel quantum defect theory (MQDT) [14,16,17].

The energy-independent symmetric matrix $A$ has six independent parameters $A_{ij}$ allowing one to explore an enormous six-dimensional parameter space. In order to simplify our analysis, we choose $A_{13}=A_{12}>0$, $A_{22}=2A_{33}$, and $A_{12}=A_{33}=A_{31}/4$. Explicitly allowing $A_{33} \neq A_{12}$ or $A_{11} \neq A_{33}$ gives qualitatively similar results in all three-body calculations described below. The particular choice $A_{22}=2A_{31}$ is made simply to illustrate the effect of a two-body quasibound state on the three-body dynamics; any $A_{22}>A_{33}$ would be sufficient for this purpose. The choice $A_{12}=A_{31}=A_{33}/4$ is arbitrary and provides strong coupling between channels modeling a broad resonance. For $A_{33}>0$, the [22] threshold is $\tanh A_{33} \approx 1/mA_{33}^2$ and $\approx 1/mA_{33}^2$, an attractive $R^{-2}$ Efimov potential appears in the three-body system near $E=\epsilon$ and $E=2\epsilon$, supporting a series of Efimov resonances.

For three atoms with positions $r_1$, $r_2$, and $r_3$, we write the mass-scaled Jacobi coordinates in the “odd-man-out” notation: $y_1^{(1)}=y_1-2y_2$, $y_2^{(1)}=2y_1+y_2$, $y_3^{(1)}=d\frac{r_1 r_2}{r_3}$ (with $d=2^{1/2}/3^{1/4}$). Other sets of Jacobi coordinates (e.g., $y_1^{(2)}$, $y_2^{(2)}$) are obtained by cyclic permutation of particles. In what follows, we omit the superscript denoting a particular choice of coordinates whenever possible. Hyperspherical coordinates are obtained by defining the hyperangle $\alpha$ as tan $\alpha=|y_1|/|y_2|$, the hyperradius $R$ as $R^2=y_1^2+y_2^2$ (which is invariant under particle permutations), and the spherical polar angles $\omega_i=(\theta_i,\phi_i)$ to point in the direction of $y_i$. The angular coordinates $\{\alpha,\omega_1,\omega_2\}$ are collectively denoted $\Omega$. The pairwise interactions are written in the basis of two-body internal states, with the third spectator particle (near any chosen two-particle coalescence point) in either state $|1\rangle$ or $|2\rangle$. Hence, if particle 1 is the spectator particle, we have the following six internal three-body product states: $\Sigma = \{ |111\rangle, |112\rangle + |121\rangle \}/\sqrt{2}, |211\rangle, |122\rangle, (|121\rangle + |211\rangle)/\sqrt{2}, |222\rangle \}$ with energies $|E_\Sigma|=\{0, \epsilon, \epsilon, 2\epsilon, 2\epsilon, 3\epsilon\}$. In the multichannel generalization [18] of the adiabatic hyperspherical method [19], we seek solutions to the following matrix equation written in the $|\Sigma\rangle$ basis:

$$\left( \frac{\Lambda^2+15/4}{2\mu_R^2} + E_{\text{th}} + V(R,\Omega) - U(R) \right) \Phi(R,\Omega) = 0.$$ \hspace{1cm} (2)

Here, $\Lambda$ is the grand angular momentum operator [20], $E_{\text{th}}$ is a diagonal matrix, $[E_{\text{th}}]_{\Sigma \Sigma} = \delta_{\Sigma \Sigma} E_{\Sigma}$, and $V(R,\Omega)$ is the sum of matrices $v^{(i)}$ for each pairwise interaction. The three-body reduced mass is $\mu=m/\sqrt{3}$. Solutions to Eq. (2) give a spectrum of eigenvalues $U_{\Sigma}(R)$, which we recast in terms of a new variable $v_{\Sigma}^\alpha = \mu_R^2 U_{\Sigma}(R) - E_{\Sigma}$, $-15/4$. The potentials $U_{\Sigma}(R)$ appear in radial equations of the form (ignoring nonadiabatic effects) $- \frac{d^2 v_{\Sigma}}{dR^2} + U_{\Sigma}(R) = EF_{\sigma}(R)$.

Here, we solve Eq. (2) using a hyperangular Green’s function. The corresponding Lippmann-Schwinger (LS) equation for the $\Sigma$ component of $\Phi$ reads

$$\Phi_{\Sigma}(R,\Omega) = \sum_{\Sigma',k} \left[ g^{\Sigma'\Sigma}_{\Sigma'k} (\alpha,\alpha') Y_{\Sigma'k\theta}(\alpha') \right] \times \left[ \Phi_{\Sigma'}(R,\Omega') \right] \times Y_{\Sigma'k\theta}(\alpha')$$ \hspace{1cm} (3)

where components of the free-space (diagonal) hyperangular Green’s function $G(\Omega,\Omega')$ satisfy $[\Lambda^2-\nu_{\Sigma}(\alpha) + 4]G_{\Sigma}(\Omega,\Omega') = \delta(\Omega,\Omega')$. Postponing the full derivation to a later publication [21], we give this solution (for the first time) [22]:

$$G_{\Sigma}(\Omega,\Omega') = \sum_{\Sigma',l_1 l_2 l_3} \left[ g^{\Sigma'\Sigma}_{\Sigma'k} (\alpha,\alpha') Y_{\Sigma'k\theta}(\alpha') \right] \times Y^\dagger_{\Sigma'k\theta}(\alpha) Y_{\Sigma'k\theta}(\alpha') \times \left[ \Phi_{\Sigma'}(R,\Omega') \right]$$ \hspace{1cm} (4)

with $g^{\Sigma'\Sigma}_{\Sigma'k} (\alpha,\alpha') = N_{\Sigma',l_1 l_2 l_3} f^{(1)}(\alpha) (\alpha') f^{(1)}(\alpha')$. The normalization constant is $N_{\Sigma',l_1 l_2} = \sqrt{2 \Gamma(l_1+\frac{3}{2}) \Gamma(l_2+\frac{3}{2})}$. The LS equation (3) is then solved by evaluating the integral over $\psi_{\Sigma\Sigma'}^{(k)}$ in the coordinate system where $y_1^{(i)} \propto |\vec{r}_1-\vec{r}_2| \times R \sin a^{(i)}$. The zero-range s-wave interaction immediately selects $l_1=0$ for the two interacting particles and $l_2=L$. For this Rapid Communication, we confine our study to states with total orbital angular momentum $L=0$. For equal-mass particles, in the limit $a^{(i)} \to 0$ we have $a^{(i)} = a^{(i)} = \pi/3$; the LS equation reduces to a matrix equation of the form [18]

$$\left( \frac{3^{1/4}}{2^{1/2} R} (M^{(1)} + M^{(2)} P_+ + M^{(3)} P_-) - 1 \right) \hat{c}^{(1)} = 0,$$ \hspace{1cm} (5)

where, for bosons,
two identical bosons and one distinguishable particle

EFIMOV STATES EMBEDDED IN THE THREE-BODY \ldots

\[ M_{\Sigma i}^{(i)} = \begin{cases} A_{\Sigma i}^{(i)}, & i = 1, \\ \lambda_2 \cot(\lambda_2 \pi/2), & i = 2, 3. \end{cases} \]

The vector associated with the \( n \)th eigenstate, \( C_{\Sigma n}^{(i)} \) in Eq. (6), is defined by the boundary and normalization conditions

\[ C_{\Sigma n}^{(i)} = \lim_{\epsilon \to 0} \frac{\delta(\epsilon \Phi_{\Sigma n})}{\partial \epsilon}, \quad \text{and} \quad \sum_n \langle \Phi_{\Sigma n} | \Phi_{\Sigma n} \rangle = 1. \]

We have rewritten the eigenvalue as \( \nu_2 = \lambda_2 - 2 \) purely for convenience, and \( P_+ \) and \( P_- \) perform cyclic and anticyclic particle permutations, respectively, upon the basis \( \{\Phi_{\Sigma i}\} \). Zeros of the determinant of the matrix in Eq. (6) yield the eigenvalues \( \lambda_2^2 = 2\mu R^2 |U_0(R) - E_2| + 1/4 \).

As mentioned before, by allowing \( \epsilon \) to vary with the magnetic field, it is possible to make a quasi-bound two-body state degenerate with the \( \sigma = 2 \) threshold. This occurs when \( \epsilon \to 1/(m R_{13}^2) \) as illustrated in Fig. 1. Under these conditions, provided that \( |A_{13}| \ll A_{33} \), an Efimov potential appears at both the \( E = \epsilon \) and \( E = 2\epsilon \) three-body thresholds. In Fig. 2(a) we show the lowest 300 adiabatic potential curves up to \( E = 3.5\epsilon \). Note the collection of three-body curves converging to the various three-body scattering thresholds \( \{E_3\} \), corresponding asymptotically to three free atoms in internal states given by \( \{\Sigma_i\} \). In Fig. 2(b), which shows in detail the three-body potentials near \( E = \epsilon \), the Efimov potential appears as an attractive \( \text{adiabatic potential} \) connected through a series of sharp avoided crossings. The eigenvalues \( \lambda_2^2 = \lambda_2^2 - 2\mu R^2 \epsilon \) corresponding to this diabatic potential are shown in Fig. 2(c) to converge to the universal value \( \lambda_2^2 \to -0.171145 = -\kappa_0^2 \). Note that this universal value is appropriate for two identical bosons interacting resonantly with a third distinguishable particle of equal mass \([24,25]\) and is consistent with the fact that the \( E = \epsilon \) threshold corresponds to atoms in internal states \( \{112\} - \{121\} \) \( \sqrt{2} \) and \( \{211\} \).

The lifetime of Efimov states near \( E = \epsilon \) is limited by the lifetime of the resonant two-body quasibound state (see Fig. 1). We find for \( A_{13} \ll A_{33} \) that the quasibound two-body state lifetime scales as \( (A_{33}/A_{13})^2 \). This two-body lifetime in turn controls the radial widths of avoided crossings at large \( R \). This is understood qualitatively by noting that when \( A_{13} \) is sizable, direct inelastic transitions between \( |\sigma = 3\rangle \) and \( |\sigma = 1\rangle \) states dominate over two-step transitions via the intermediate \( |\sigma = 2\rangle \) state, where the presence of the quasibound two-body state at energy \( E = \epsilon \) strongly affects the three-body dynamics. In the limit \( A_{13} \to 0 \), we find that inelastic transitions will occur only for \( R \approx A_{33} \) due to broader avoided crossings whose widths are controlled by the couplings \( A_{12} \) and \( A_{23} \). As all transitions occur at short range, the width of each successive Efimov state scales with the same geometric factor as the energy: \( \Gamma_n/\Gamma_{n-1} = E_n/E_{n-1} = e^{2\pi i \kappa_0} \).

Experimentally, the resolution of spectroscopic techniques is limited by the lifetime of the gas. In the present scheme, atoms spend time near \( E = 0 \), where the interaction is not resonant and the gas is expected to be stable with respect to the approximate \( a^3 \) scaling law for three-body recombinations. Photons with energy \( \hbar \omega < \epsilon \) are then introduced to associate Efimov trimers directly. Note that since \( \hbar \omega < \epsilon \), two-body collisions at the \( E = \epsilon \) threshold are not energetically allowed. It may be possible, therefore, to probe Efimov resonances attached to excited three-body thresholds for times long enough to resolve a second resonant feature in either photoabsorption or atom loss. Further, the geometric scaling factor \( e^{2\pi i \kappa_0} \) could be made more favorable by either using heteronuclear mixtures of atoms, capitalizing on mass ratios different from unity \([1,25,26]\), or by considering atoms with more than two internal states and placing a quasibound two-body state at a scattering threshold of the form \([22]\), recovering the bosonic scaling factor \( e^{2\pi i \kappa_0} \approx 22.7 \).

In order for the Efimov states to persist, it is sufficient to show that the positive-definite adiabatic correction \( -Q(R) = \frac{1}{8 \pi} \frac{1}{\sqrt{R}} \langle R | \Phi(R) \rangle \) corresponding to the Efimov potential falls off faster than \( R^{-2} \). Following a multichannel generalization of the method used in \([23]\), we find that this correction for the Efimov potential falls off as \( R^{-3} \), consistent with the single-channel result and allowing these states to persist.

In Fig. 2(a), the series of avoided crossings near \( 0.6\epsilon \) is a
direct result of the quasibound two-body state attached to the |σ=2⟩ threshold in Fig. 1. The radial width of these avoided crossings is controlled by the width of the two-body resonance. For a broad resonance, three-body collisions near this energy couple strongly to the two-body Fano-Feshbach resonance through this series of avoided crossings. As the two-body resonance becomes narrower, the avoided crossings become sharper, converging to a true atom-dimer scattering threshold in the limit of an infinitely narrow resonance. Note that the degeneracy of a quasibound two-body state with the E=0 scattering threshold results in the usual Fano-Feshbach resonance and leads to the series of Efimov states that were interpreted as shape resonances in Ref. [6].

To summarize, we have identified a class of Efimov states embedded in the three-body continuum. The hyperradial potentials supporting these states have universal properties consistent with the symmetry constraints implied by the internal degrees of freedom of the three-atom system and can further be understood in terms of relevant two-body length scales. Further, we have identified the parameter A13 responsible for the long-range coupling which limits the lifetime of these Efimov states and have found that the repulsive diagonal nonadiabatic correction falls off as R−3, consistent with the single-channel result. We stress that since the potential supporting these states appears when a quasibound two-body state is degenerate with an excited two-body threshold, the open-channel scattering length in general will not be resonant, and the gas is expected to be stable with respect to the general d4 scaling of recombination. We postulate that it may be possible to observe these states by spectroscopic techniques, perhaps with sufficient accuracy to measure two Efimov resonances.

We thank D. Blume and J. H. Macek for useful discussions during the early stages of this work. This work is supported by the National Science Foundation.

[9] A “threshold” is the energy at which a particular scattering process becomes energetically allowed.
[11] This stipulation has a caveat that in the matrix A of Eq. (1), A13=≠A33.
